The Knife

(Silent Shout)

"Before starting The Knife, we were working at Intel Stockholm on cache coherence for Xeon. It was mentally stimulating and Silent Shout is a homage to that time.

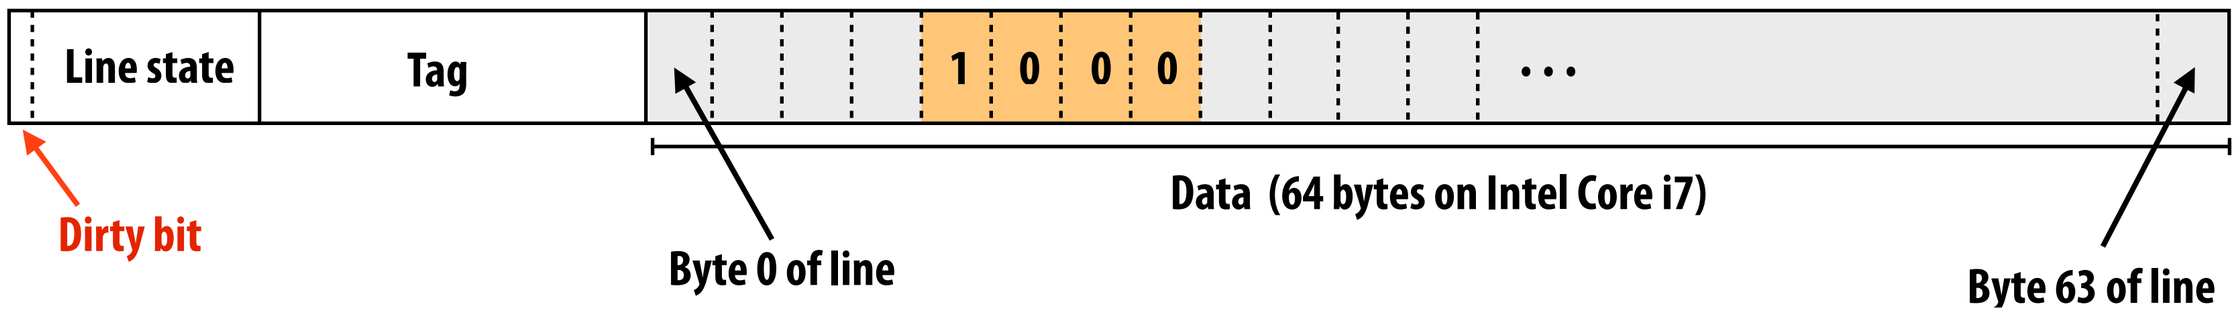
- Karin Dreijer Andersson

Cache design review

Let's say your code executes `int x = 1;`

(Assume for simplicity x corresponds to the address 0x12345604 in memory... it's not stored in a register)

One Cache Line:

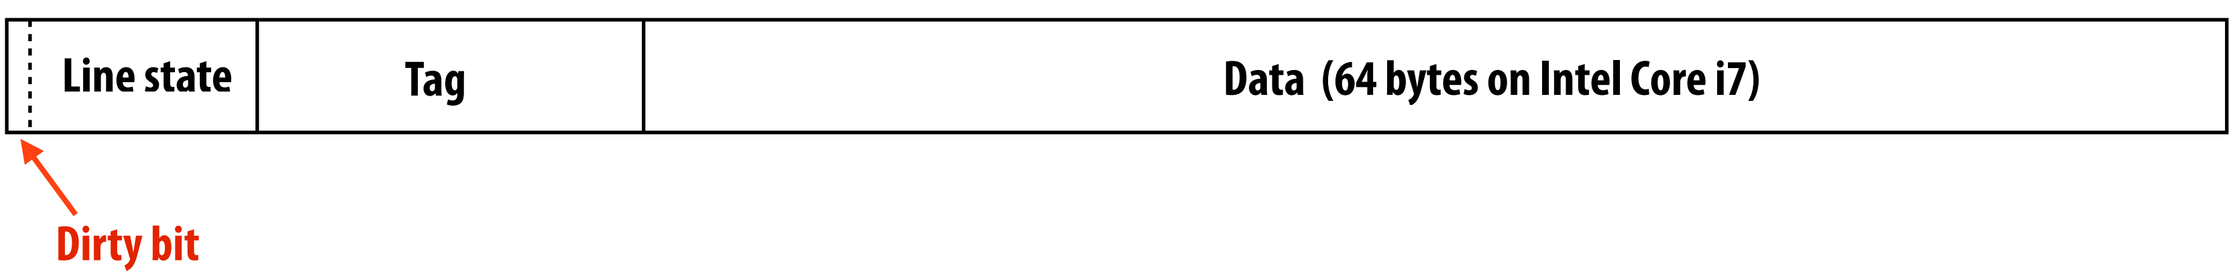


- Review
  - Write back vs. write-through cache
  - Write allocate vs. write-no-allocate cache

Review: write miss behavior of write-allocate, write-back cache (uniprocessor case)

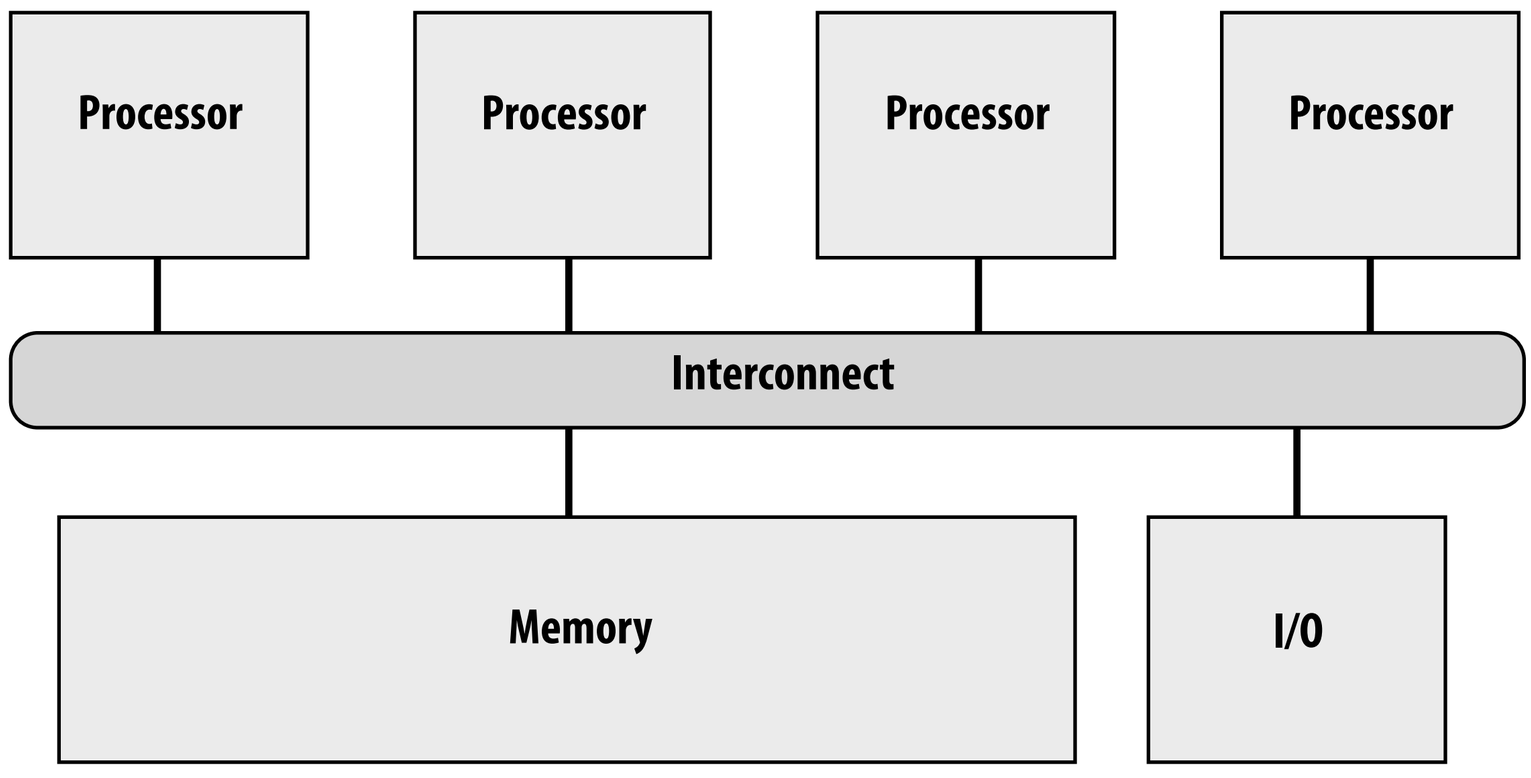
Example: processor executes `int x = 1;`

1. **Processor performs write to address in line that is not resident in cache**
2. **Cache loads line from memory ("allocate line in cache")**
3. **One word in cache is updated**
4. **Cache line is marked as dirty**



A shared memory multi-processor

- Processors read and write to shared variables
  - More precisely: processors issue load and store instructions
- A reasonable expectation of memory is:
  - Reading a value at address X should return the last value written to address X *by any processor*



(A nice and simple view of four processors and their shared address space)

The cache coherence problem

Modern processors replicate contents of memory in local caches

As a result of writes, processors can observe different values for the same memory location

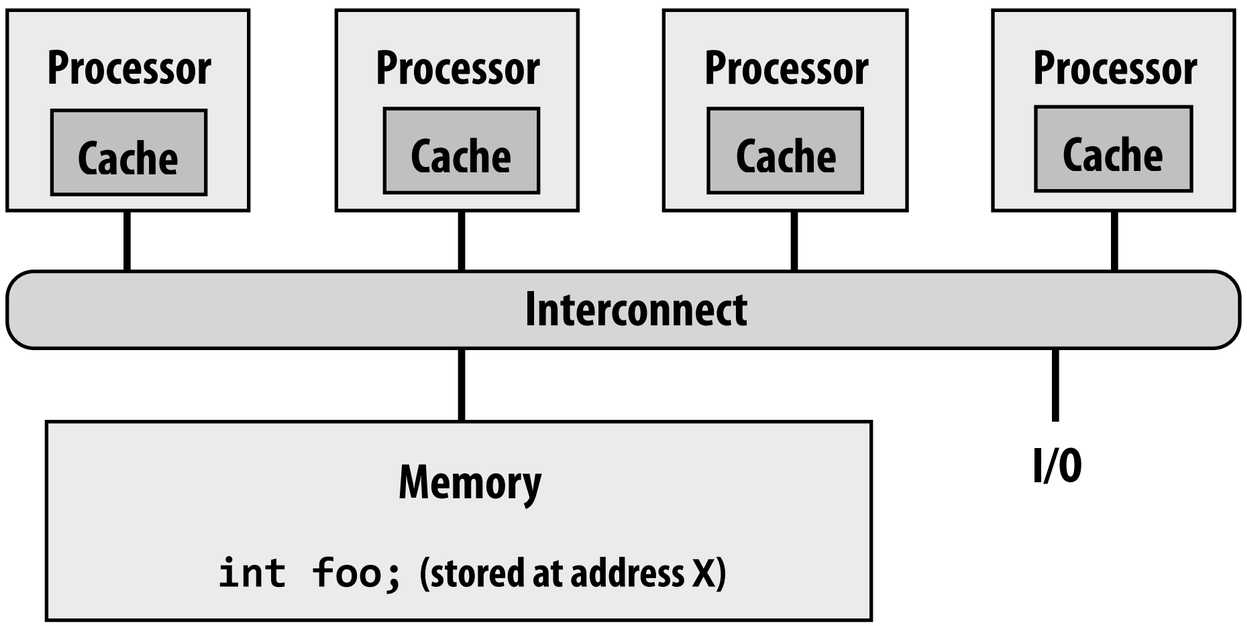


Chart at right shows the value of variable `foo` (stored at address X) in main memory and in each processor's cache **

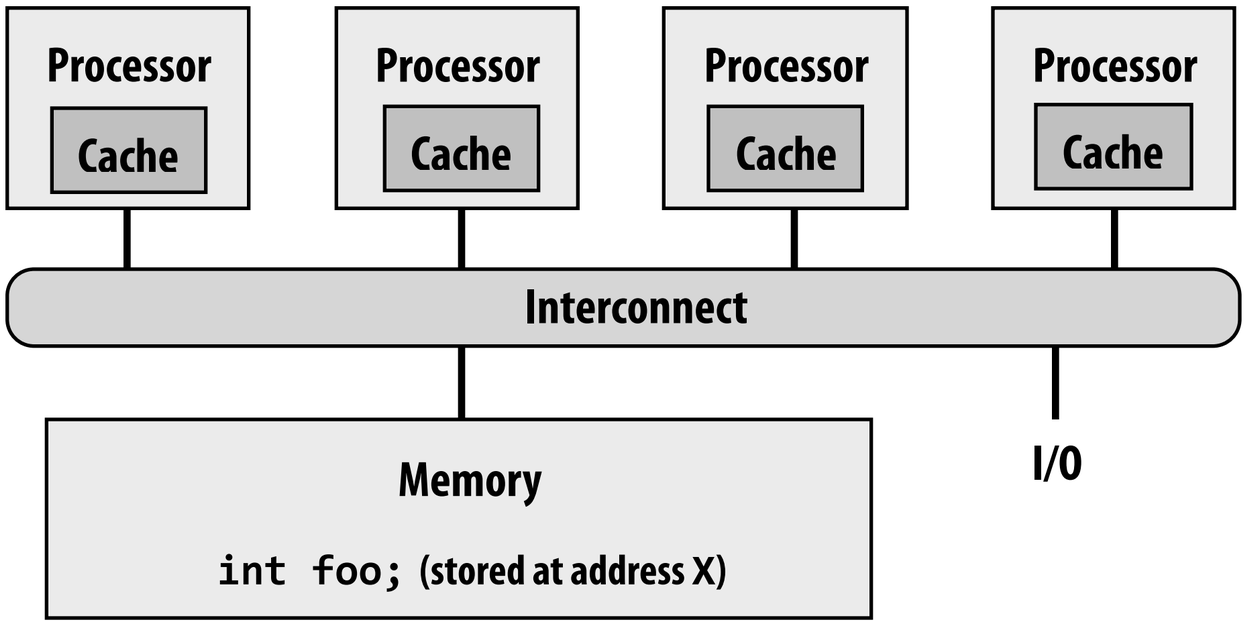
Assume that beginning value of `foo` (value stored at address X) is 0

**** Assume write-back cache behavior**

Action	P1 $	P2 $	P3 $	P4 $	mem[X]
					0
P1 load X	0 miss				0
P2 load X	0	0 miss			0
P1 store X	1	0			0
P3 load X	1	0	0 miss		0
P3 store X	1	0	2		0
P2 load X	1	0 hit	2		0
P1 load Y (assume this load causes eviction of X)		0	2		1

The cache coherence problem



How is this problem different from the mutual exclusion problem?

Can you fix the problem by adding locks to your program?

Chart shows the value of `foo` (a program variable stored at address X) in main memory, and also in each processor's cache **

**** Assumes write-back cache behavior**

Action	P1 $	P2 $	P3 $	P4 $	mem[X]
					0
P1 load X	0 miss				0
P2 load X	0	0 miss			0
P1 store X	1	0			0
P3 load X	1	0	0 miss		0
P3 store X	1	0	2		0
P2 load X	1	0 hit	2		0
P1 load Y (assume this load causes eviction of X)		0	2		1

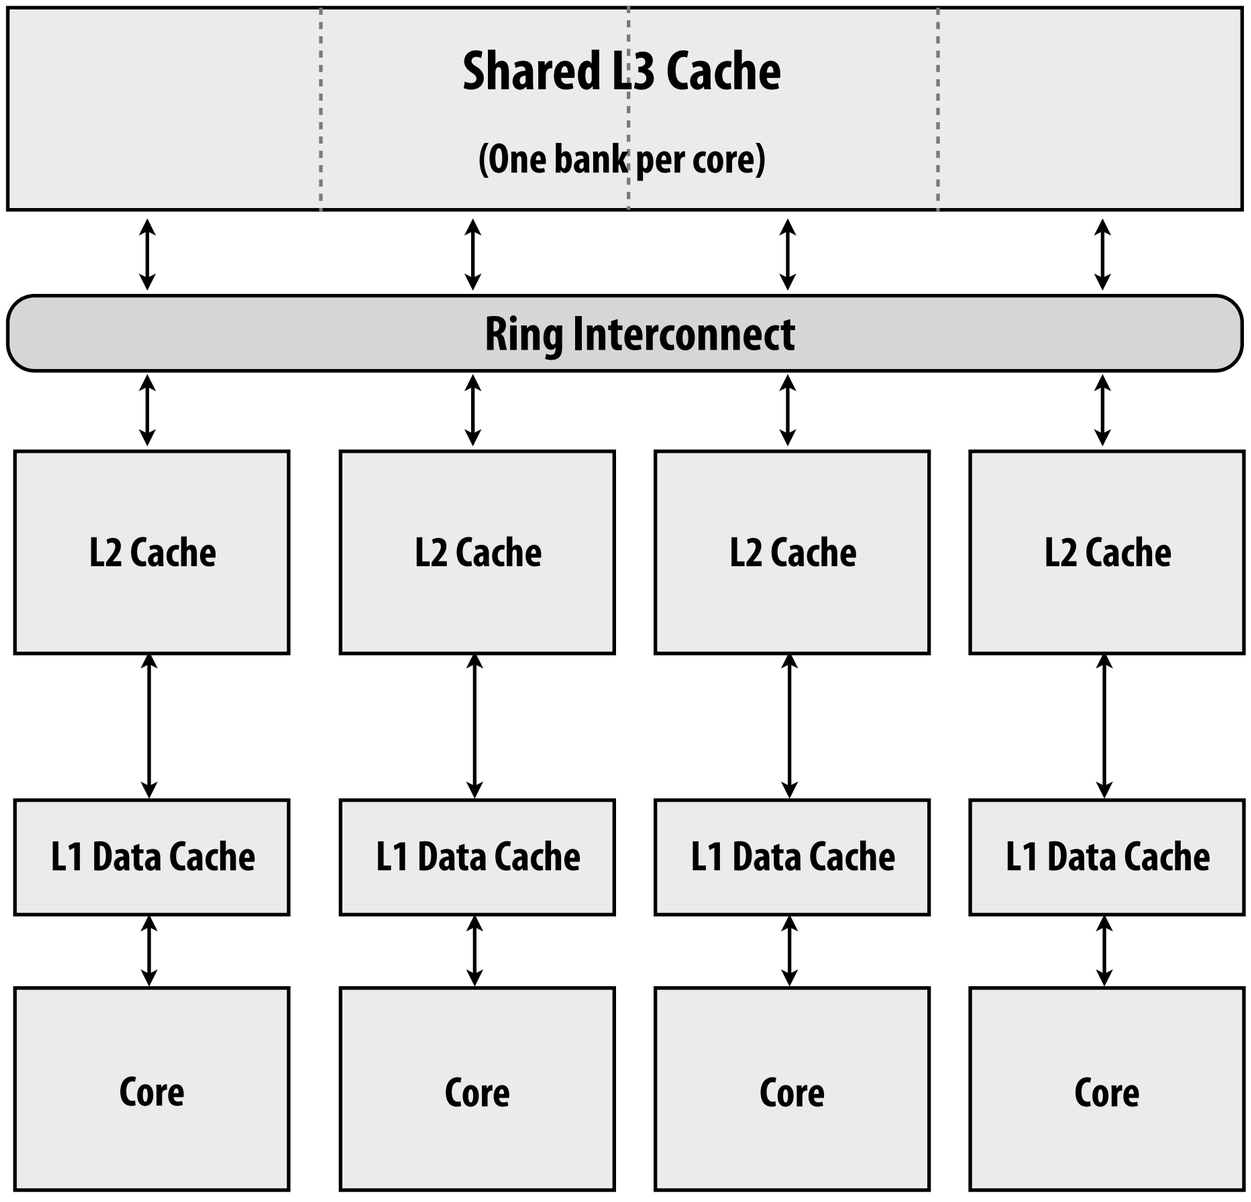
The cache coherence problem

- Intuitive behavior for memory system: reading value at address X should return the last value written to address X *by any processor.*

- Coherence problem exists because there is both global storage (main memory) and per-processor local storage (processor caches) implementing the abstraction of a single shared address space.

Cache hierarchy of Intel Core i7 CPU (2013)

64 byte cache line size



L3: (per chip)
8 MB, inclusive
16-way set associative
32B / clock per bank
26-31 cycle latency

L2: (private per core)
256 KB
8-way set associative, write back
32B / clock, 12 cycle latency
Up to 16 outstanding misses

L1: (private per core)
32 KB
8-way set associative, write back
2 x 16B loads + 1 x 16B store per clock
4-6 cycle latency
Up to 10 outstanding misses

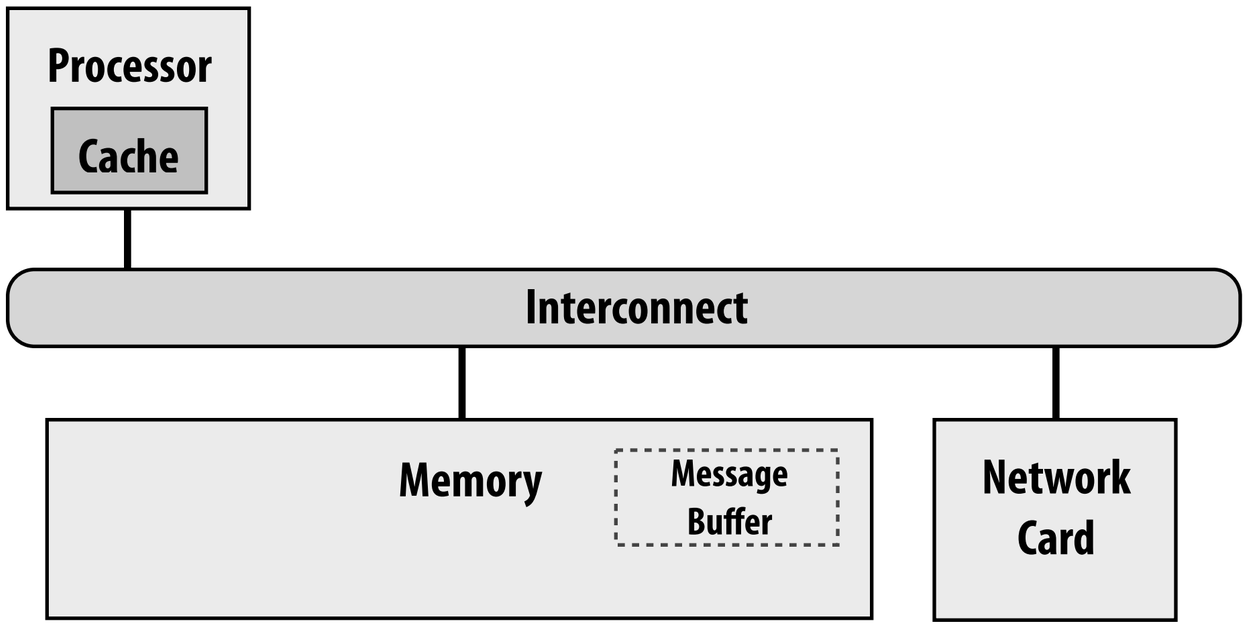
Intuitive expectation of shared memory

- Intuitive behavior for memory system: reading value at address X should return the last value written to address X *by any processor.*

- On a uniprocessor, providing this behavior is fairly simple, since writes typically come from one client: the processor
  - Exception: device I/O via direct memory access (DMA)

Coherence is an issue in a single CPU system

Consider I/O device performing DMA data transfer



Case 1:
Processor writes to buffer in main memory
Processor tells network card to async send buffer
Problem: network card many transfer stale data if processor's writes (reflected in cached copy of data) are not flushed to memory

Case 2:
Network card receives message
Network card copies message in buffer in main memory using DMA transfer
Card notifies CPU msg was received, buffer ready to read
Problem: CPU may read stale data if addresses updated by network card happen to be in cache.

- **Common solutions:**
  - **CPU writes to shared buffers using uncached stores (e.g., driver code)**
  - **OS support:**
    - **Mark virtual memory pages containing shared buffers as not-cachable**
    - **Explicitly flush pages from cache when I/O completes**

- **In practice, DMA transfers are infrequent compared to CPU loads and stores (so these heavyweight solutions are acceptable)**

Problems with the intuition

- Intuitive behavior: reading value at address X should return the last value written to address X *by any processor.*

- What does "last" mean?
  - What if two processors write at the same time?
  - What if a write by P1 is followed by a read from P2 so close in time, it's impossible to communicate the occurrence of the write to P2 in time?

- In a sequential program, "last" is determined by program order (not time)
  - Holds true within one thread of a parallel program
  - But we need to come up with a meaningful way to describe order across threads in a parallel program

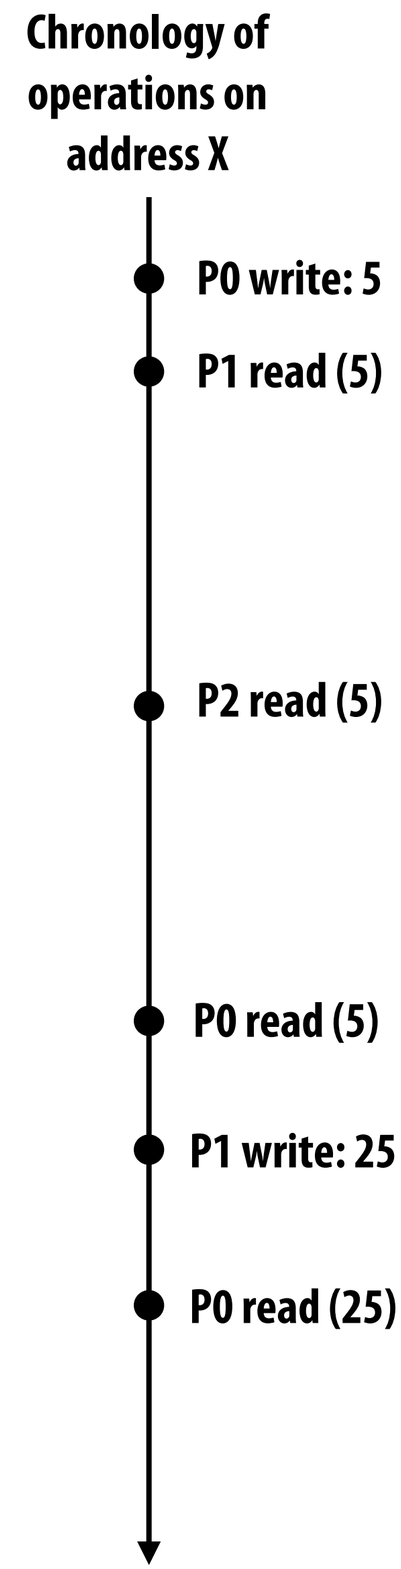
Definition: coherence

A memory system is coherent if:

The results of a parallel program's execution are such that for each memory location, there is a hypothetical serial order of all program operations (executed by all processors) to the location that is consistent with the results of execution, and:

1. **Memory operations issued by any one processor occur in the order issued by the processor**

2. **The value returned by a read is the value written by the last write to the location… as given by the serial order**



Definition: coherence (said differently)

A memory system is coherent if:

1. **A read by processor P to address X that follows a write by P to address X, should return the value of the write by P** *(assuming no other processor wrote to X in between)*

2. **A read by processor P1 to address X that follows a write by processing processor P2 to X returns the written value... if the read and write are sufficiently separated in time** *(assuming no other write to X occurs in between)*

3. **Writes to the same address are serialized: two writes to address X by any two processors are observed in the same order by all processors.**

   (Example: if values 1 and then 2 are written to address X, no processor observes X having value 2 before it has value 1)

Condition 1: obeys program order (as expected of a uniprocessor system)

Condition 2: "write propagation": Notification of a write must eventually get to the other processors. Note that precisely when information about the write is propagated is not specified in the definition of coherence.

Condition 3: "write serialization"

Write serialization

Writes to the same location are serialized: two writes to address X by any two processors are observed in the same order by all processors.

(Example: if a processor observed X having value 1 and then 2, no processor observes X having value 2 before it has value 1)

Example: P1 writes value *a* to X. Then P2 writes value *b* to X.

Consider situation where processors observe different order of writes:

Order observed by P1	Order observed by P2
x ← a	x ← b
⋮	⋮
x ← b	x ← a

In terms of the first coherence definition: there is no global ordering of loads and stores to X that is in agreement with results of this parallel program.
(you cannot put the two memory operations on a single timeline and have both processor's observations agree with the timeline)

Memory coherence vs. memory consistency

- Coherence <u>only</u> defines the behavior of reads and writes to the <u>same</u> memory location

- "Memory consistency" (a topic of next week's lecture) defines the behavior of reads and writes to <u>different</u> locations
  - Consistency deals with the "WHEN" aspect of write propagation
  - Coherence only guarantees that a write does eventually propagate

- For the purposes of this lecture:
  - If processor writes to address X and then writes to address Y. Then any processor that sees result of the write to Y also observes result of write to X.
  - Why does coherence alone not guarantee this? (hint: first bullet point)

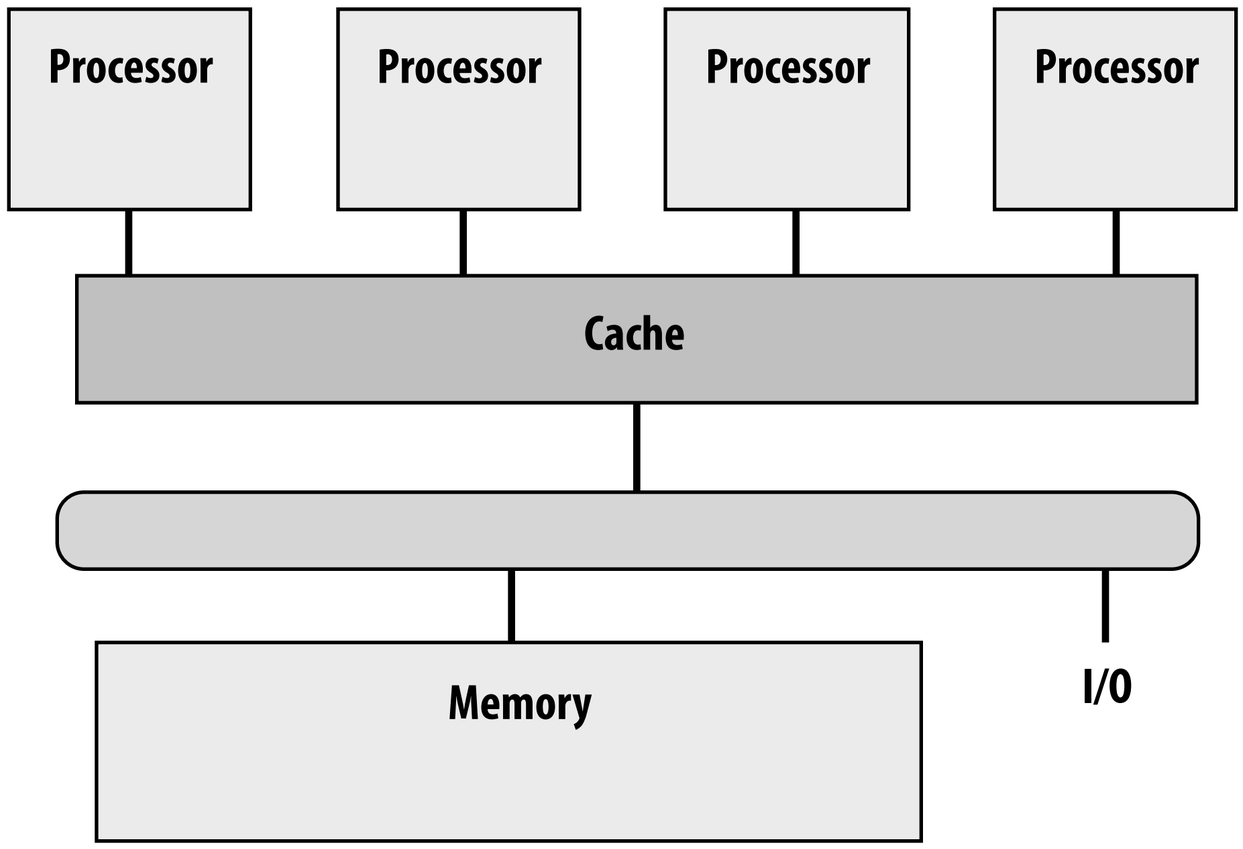
Implementing coherence

- Software-based solutions
  - OS uses page fault mechanism to propagate writes
  - Implementations provide memory coherence over clusters of workstations
  - We won't discuss these solutions

- Hardware-based solutions
  - "Snooping"-based coherence implementations (today and next class)
  - Directory-based coherence implementations (next, next class)

Shared caches: coherence made easy

- One single cache shared by all processors
  - Eliminates problem of replicating state in multiple caches
- Obvious scalability problems (the point of a cache is to be local and fast)
  - Interference / contention
- But shared caches can have benefits:
  - Facilitates fine-grained sharing (overlapping working sets)
  - Loads/stores by one processor might pre-fetch lines for another processor



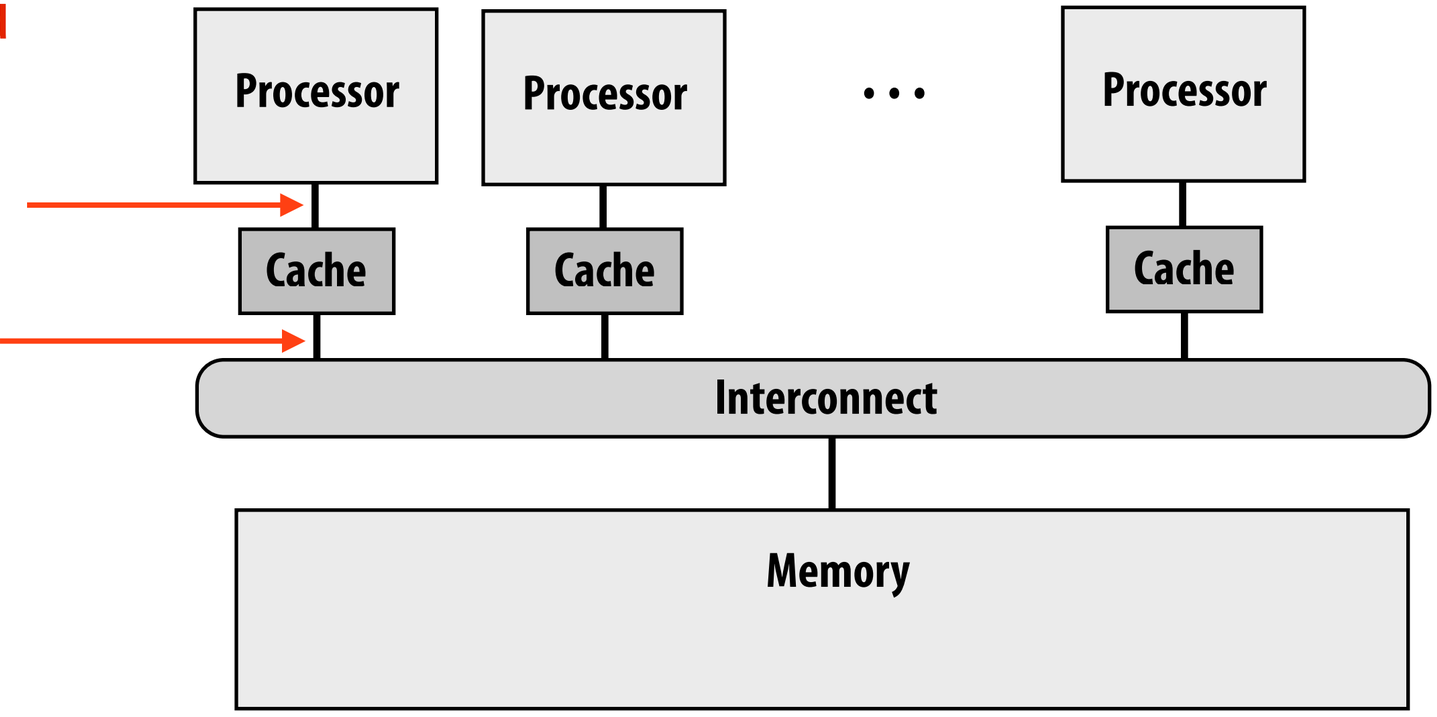
Snooping cache-coherence schemes

- Main idea: all coherence-related activity is broadcast to all processors in the system (actually, the processor's cache controllers)

- Cache controllers monitor ("they snoop") memory operations, and react accordingly to maintain memory coherence

Notice: now cache controller must respond to actions from "both ends":

1. LD/ST requests from its local processor
2. Coherence-related activity broadcast over-interconnect



Very simple coherence implementation

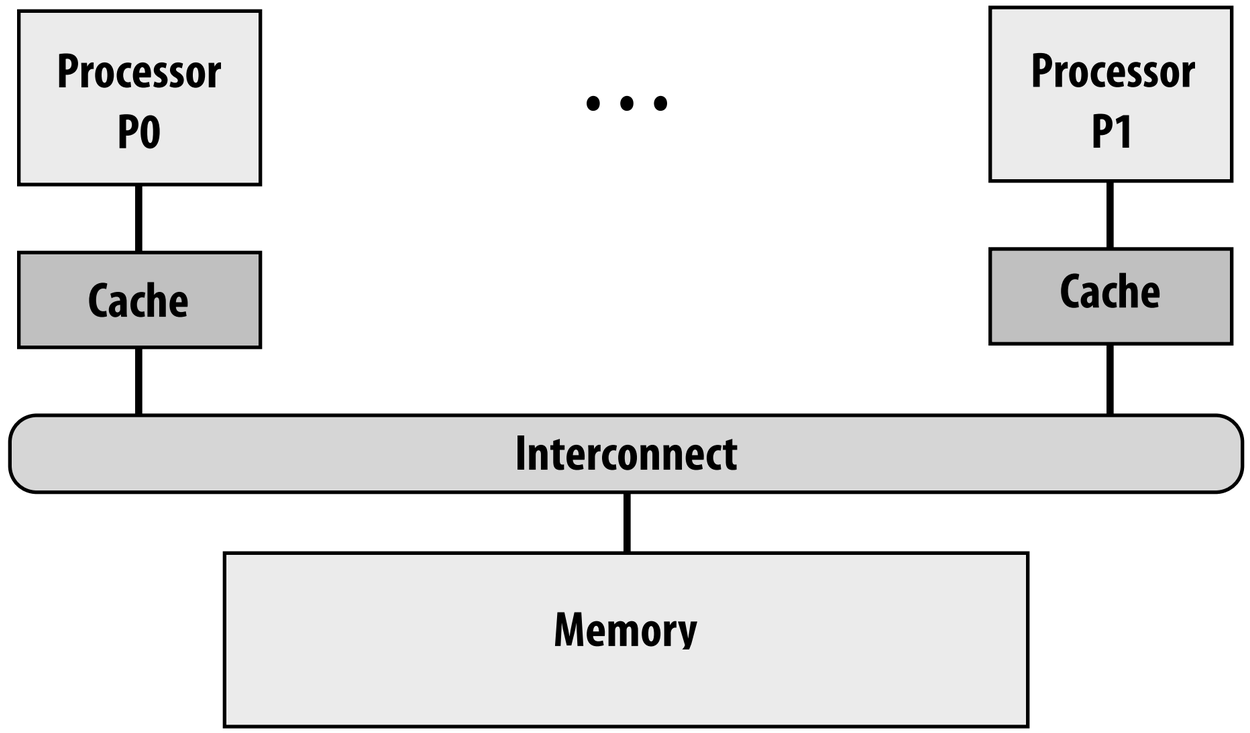
Let's assume:

1. **Write-through caches**
2. **Granularity of coherence is cache line**

Upon write, cache controller broadcasts invalidation message

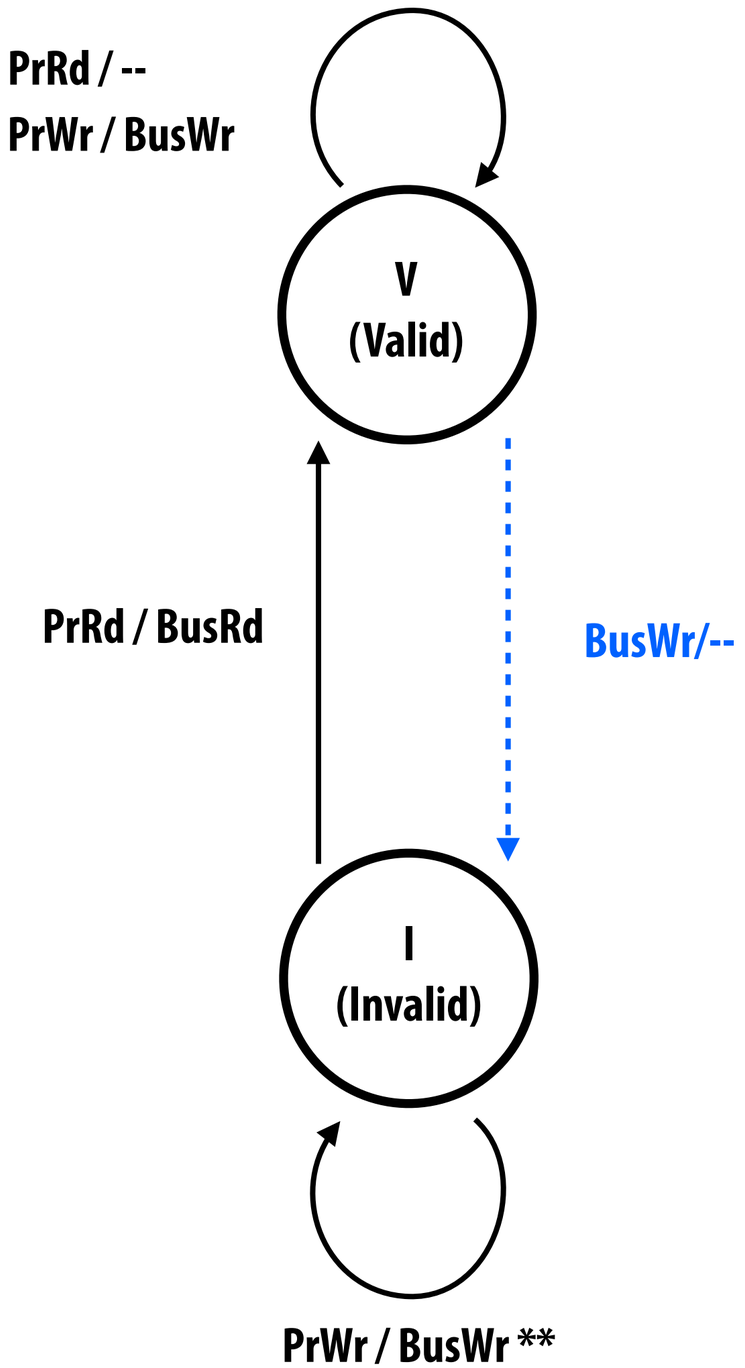
As a result, the next read from other processors will trigger cache miss

(processor retrieves updated value from memory due to write-through policy)



Action	Interconnect activity	P0 $	P1 $	mem location X
				0
P0 load X	cache miss for X	0		0
P1 load X	cache miss for X	0	0	0
P0 write 100 to X	invalidation for X	100		100
P1 load X	cache miss for X	100	100	100

Write-through invalidation: state diagram



A / B: if action A is observed by cache controller, action B is taken

Remote processor (coherence) initiated transaction

Local processor initiated transaction

Requirements of the interconnect:

1. All write transactions visible to all cache controllers
2. All write transactions visible to all cache controllers in the same order

Simplifying assumptions here:

1. Interconnect and memory transactions are atomic
2. Processor waits until previous memory operations is complete before issuing next memory operation
3. Invalidation applied immediately as part of receiving invalidation broadcast

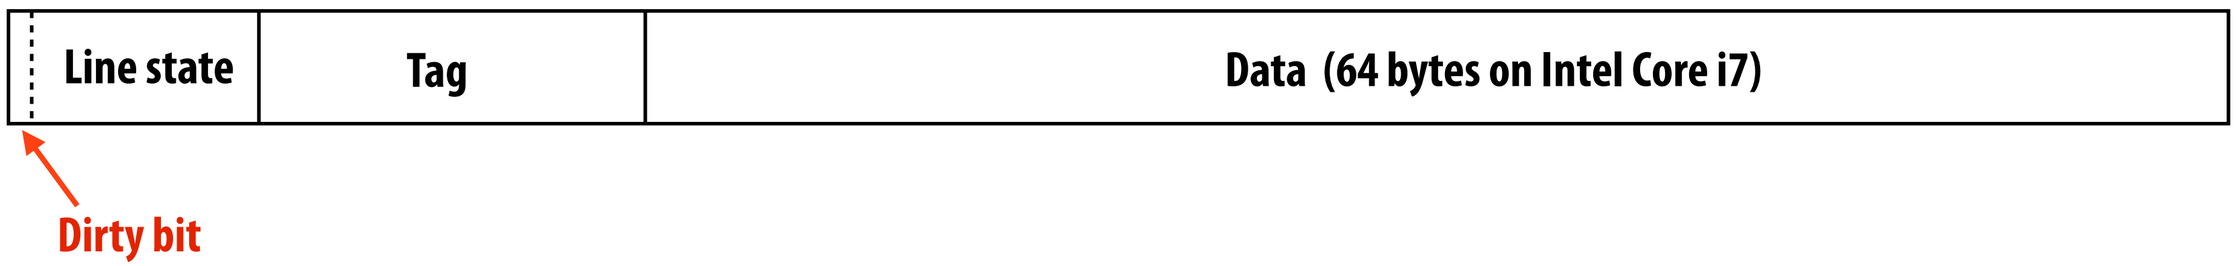
** Assumes write no-allocate policy (for simplicity)

Write-through policy is inefficient

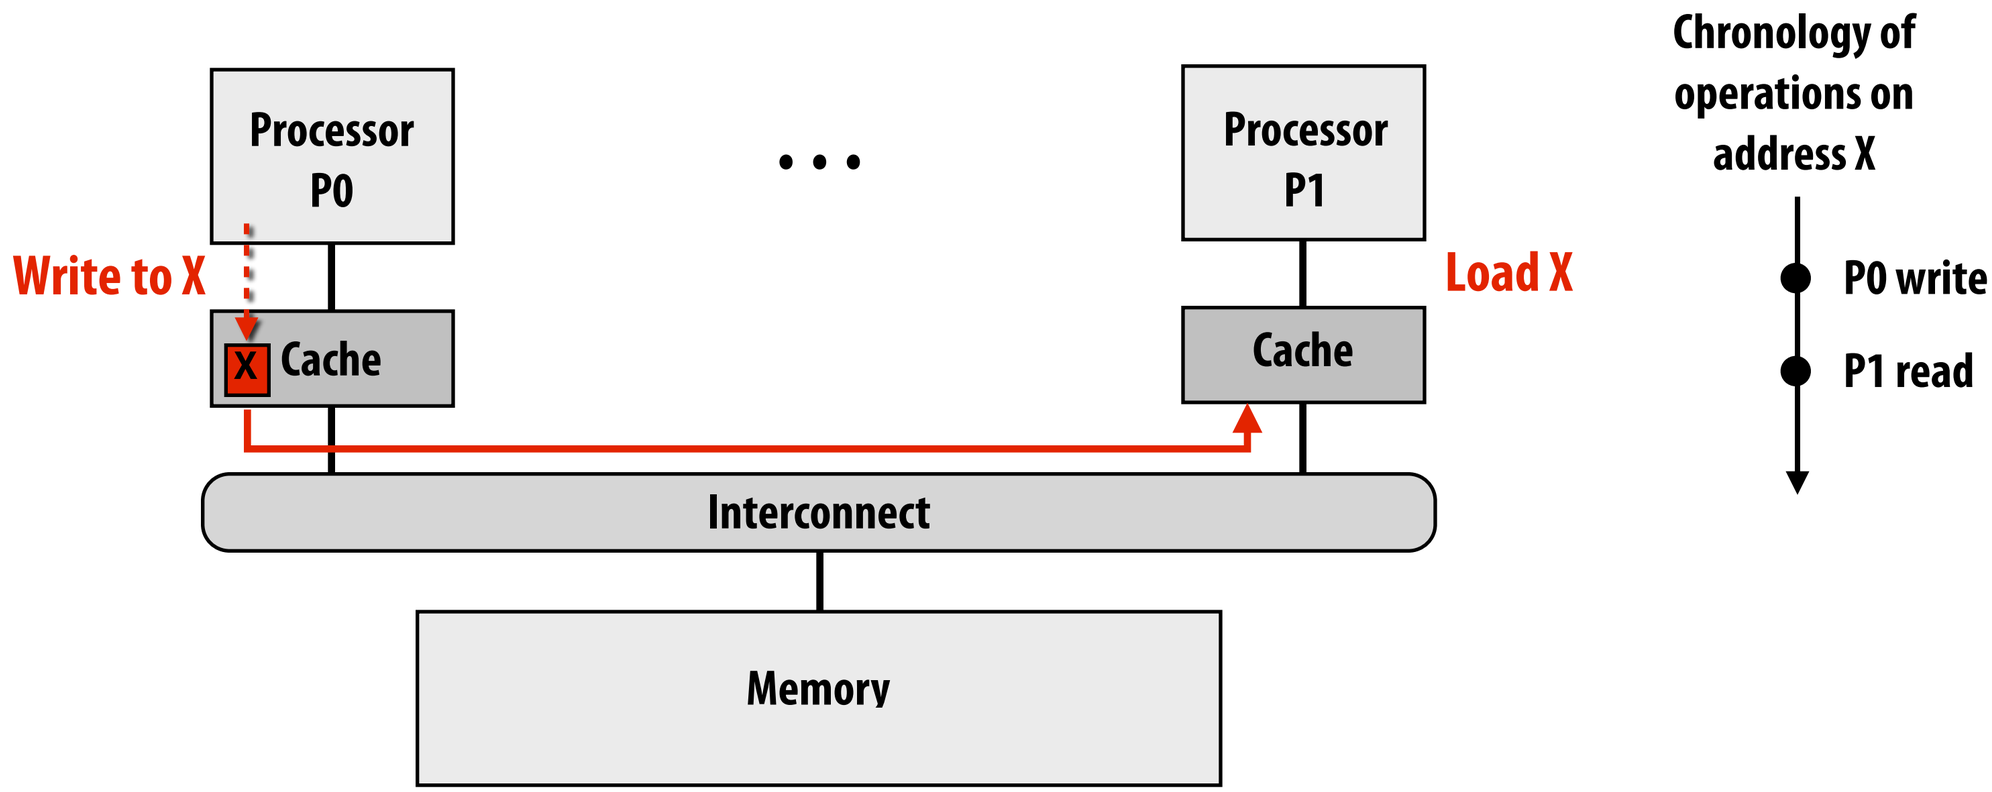
- Every write operation goes out to memory
  - Very high bandwidth requirements

- Write-back caches absorb most write traffic as cache hits
  - Significantly reduces bandwidth requirements
  - But now how do we ensure write propagation/serialization?
  - Require more sophisticated coherence protocols

Recall cache line state bits



Cache coherence with write-back caches



- Dirty state of cache line now indicates exclusive ownership
  - Exclusive: cache is only cache with a valid copy of line (so it can safely be written to)
  - Owner: cache is responsible for supplying data upon request (otherwise a load from another processor will get stale data from memory)

Invalidation-based write-back protocol

Key ideas:

- A line in the "exclusive" state can be modified without notifying the other caches
  - No other caches have the line resident, so other processors cannot read these values [without generating a memory read transaction]

- Processor can only write to lines in the exclusive state
  - If processor wants to perform a write to line that is not exclusive in cache, cache controller must first broadcast a read-exclusive transaction to all other caches

- When cache controller snoops a "read exclusive" for a line it contains
  - It must invalidate the line in its cache

MSI write-back invalidation protocol

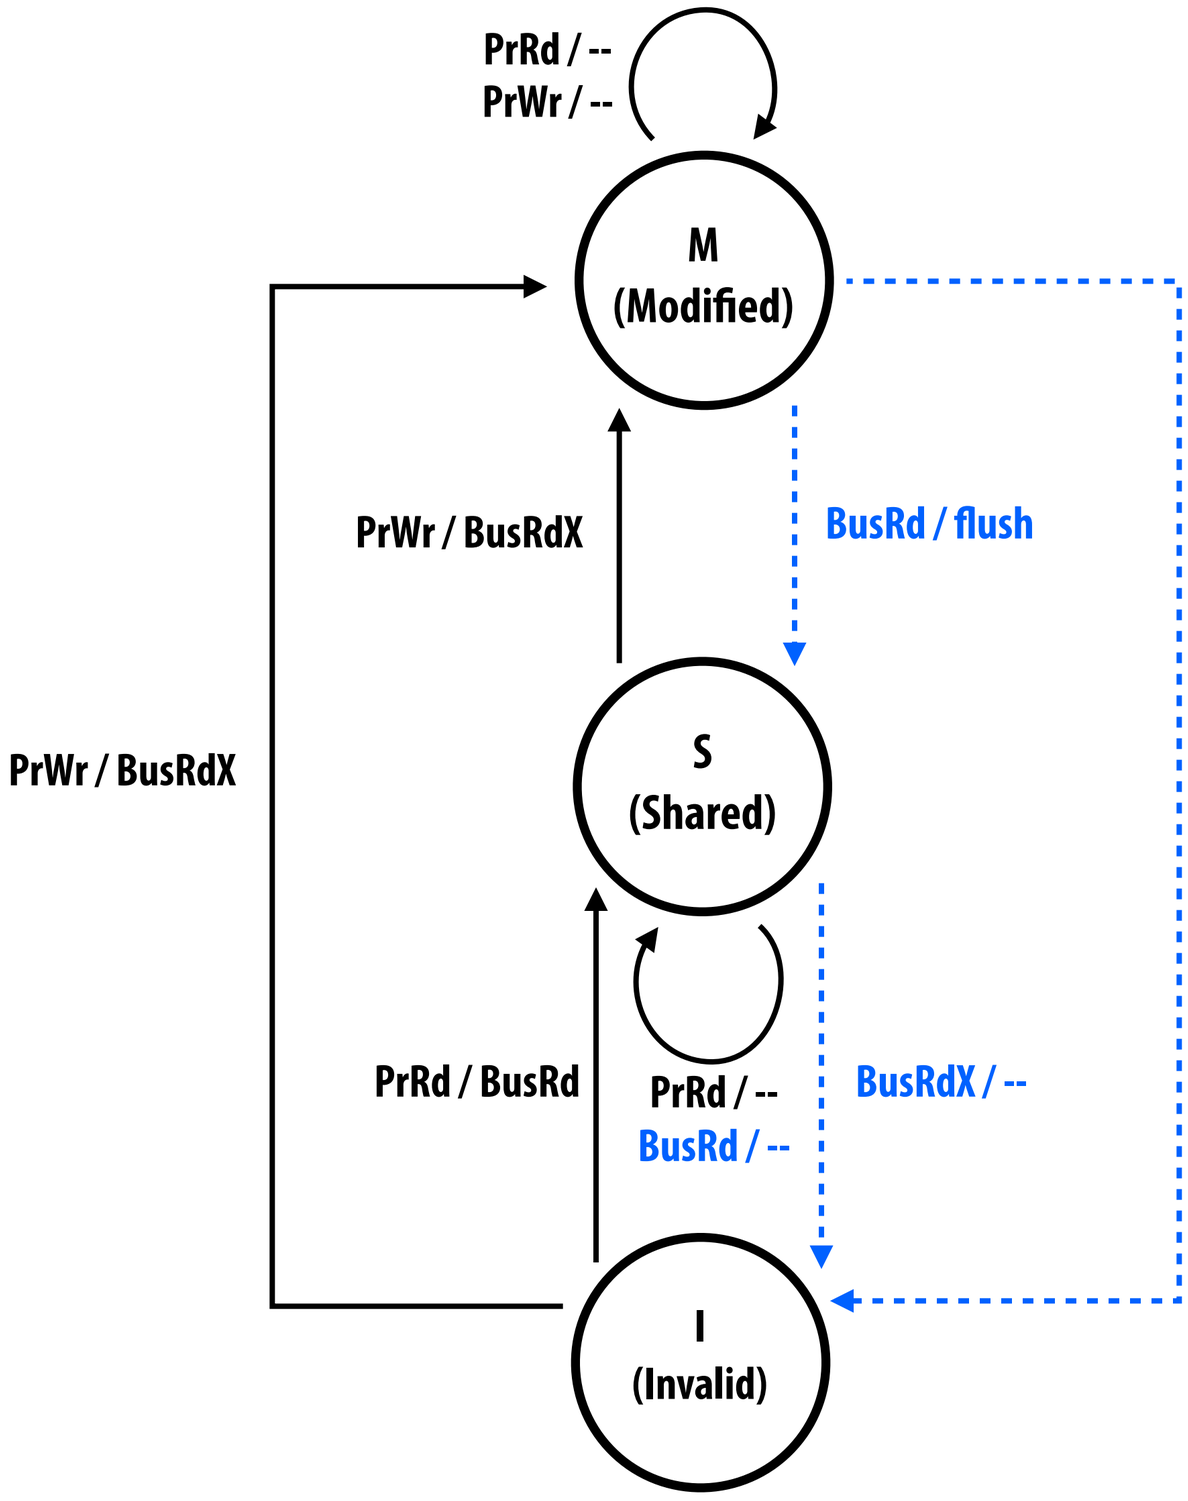
- Key tasks of protocol
  - Obtaining exclusive access for a write
  - Locating most recent copy of cache line's data on cache miss

- Three cache line states
  - Invalid (I): same as meaning of invalid in uniprocessor cache
  - Shared (S): line valid in one or more caches
  - Modified (M): line valid in exactly one cache (a.k.a. "dirty" or "exclusive" state)

- Two processor operations (triggered by local CPU)
  - PrRd (read)
  - PrWr (write)

- Three coherence-related bus transactions (from remote caches)
  - BusRd: obtain copy of line with no intent to modify
  - BusRdX: obtain copy of line with intent to modify
  - flush: write dirty line out to memory

MSI state transition diagram



A / B: if action A is observed by cache controller, action B is taken

Remote processor (coherence) initiated transaction

Local processor initiated transaction

flush = flush dirty line to memory

Note: alternative name for M state is E ("exclusive")

Invalidation-based write-back protocol

- A line in the "exclusive" state can be modified without notifying the other caches
  - No other caches have the line resident, so other processors cannot read these values [without generating a memory read transaction]

- Processor can only write to lines in the exclusive state
  - If processor performs a write to a line that is not exclusive in cache, cache controller must first broadcast a read-exclusive transaction to move the line into that state
  - Read-exclusive tells other caches about impending write ("you can't read any more, because I'm going to write")
  - Read-exclusive transaction is required even if line is valid (but not exclusive) in processor's local cache
  - Dirty state implies exclusive

- When cache controller snoops a "read exclusive" for a line it contains
  - Must invalidate the line in its cache

Does MSI satisfy coherence?

- **Write propagation**
  - Achieved via combination of invalidation on BusRdX, and flush from M-state on subsequent BusRd/BusRdX from another processors

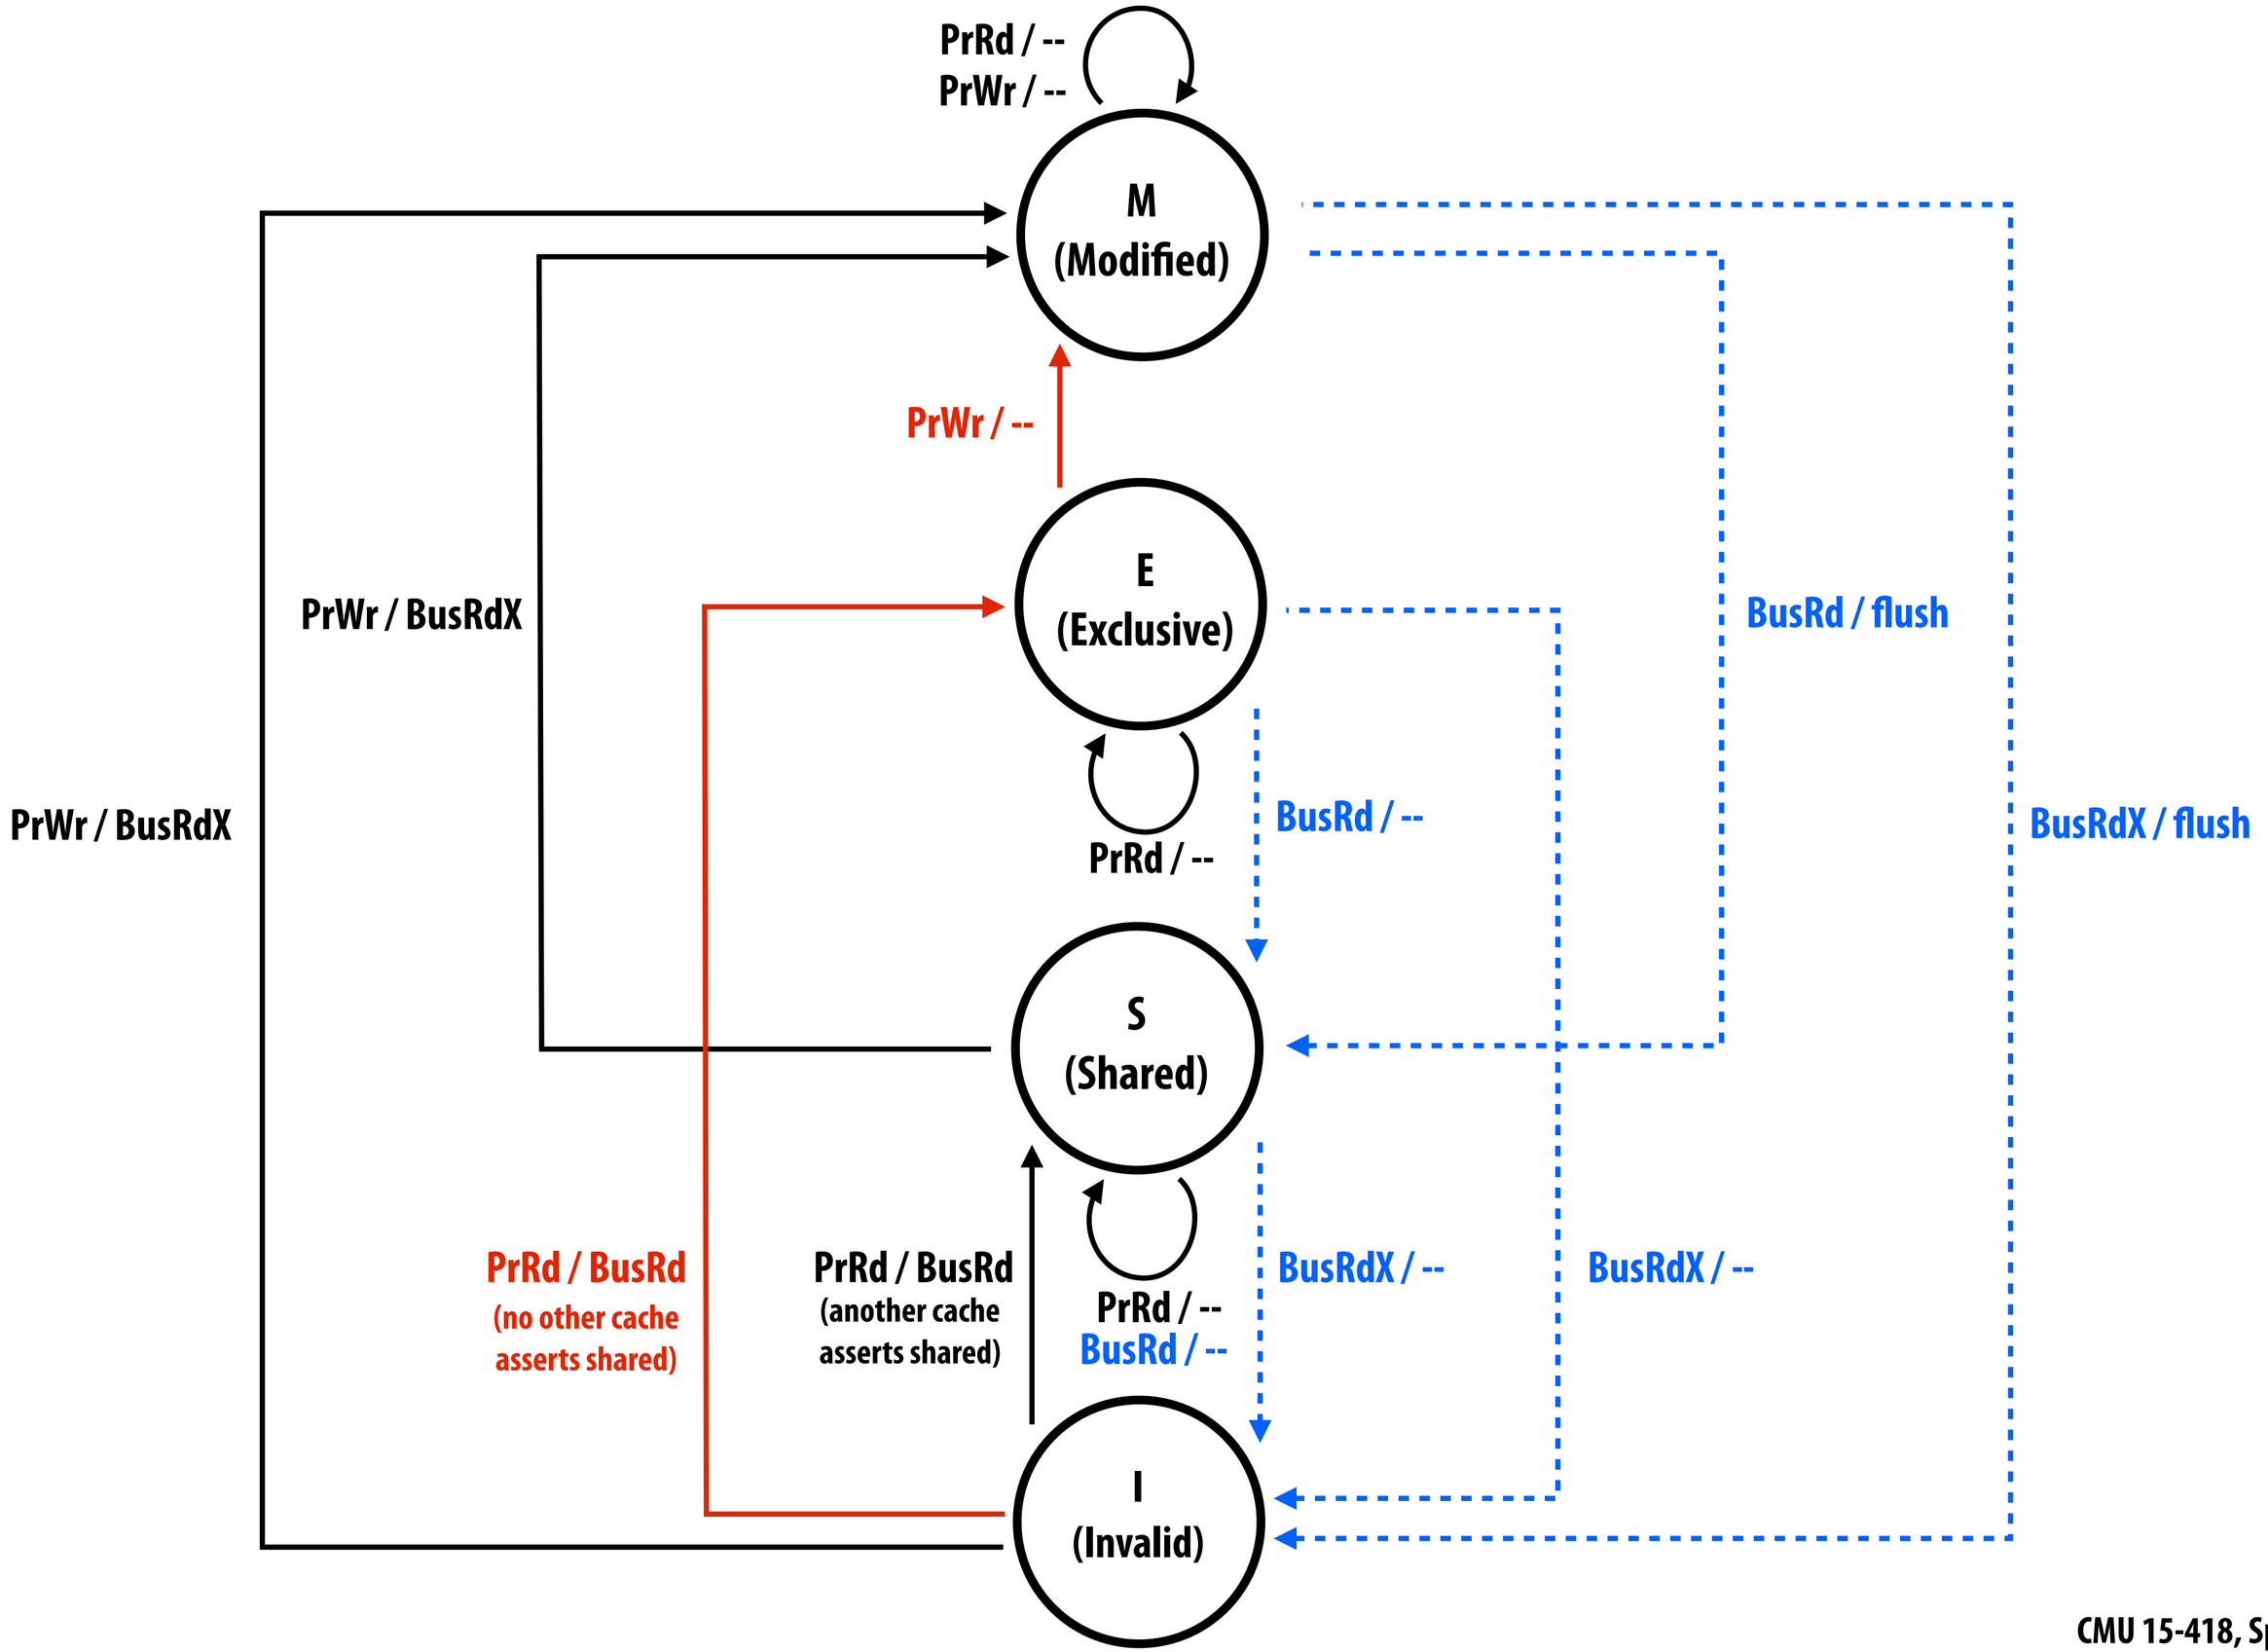
- **Write serialization**
  - Writes that appear on interconnect are ordered by the order they appear on interconnect (BusRdX)
  - Reads that appear on interconnect are ordered by order they appear on interconnect (BusRd)
  - Writes that don't appear on the interconnect (PrWr to line already in M state):
    - Sequence of writes to line comes between two interconnect transactions for the line
    - All writes in sequence performed by same processor, P (that processor certainly observes them in correct sequential order)
    - All other processors observe notification of these writes only after a interconnect transaction for the line. So all the writes come before the transaction.
    - So all processors see writes in the same order.

MESI invalidation protocol

MESI, not Messi!

- MSI requires two interconnect transactions for the common case of reading an address, then writing to it
  - Transaction 1: BusRd to move from I to S state
  - Transaction 2: BusRdX to move from S to M state
- This inefficiency exists even if application has no sharing at all
- Solution: add additional state E ("exclusive clean")
  - Line has not been modified, but only this cache has a copy of the line
  - Decouples exclusivity from line ownership (line not dirty, so copy in memory is valid copy of data)
  - Upgrade from E to M does not require an interconnect transaction

MESI state transition diagram



Lower-level choices

- Who should supply data on a cache miss when line is in the E or S state of another cache?
  - Can get cache line data from memory or can get data from another cache
  - If source is another cache, which one should provide it?
- Cache-to-cache transfers add complexity, but commonly used today to reduce both latency of access and memory bandwidth requires

Increasing efficiency (and complexity)

- MESIF (5-stage invalidation-based protocol)
  - Like MESI, but one cache holds shared line in F state rather than S (F="forward")
  - Cache with line in F state services miss
  - Simplifies decision of which cache should service miss (basic MESI: all caches respond)
  - Used by Intel processors

- MOESI (5-stage invalidation-based protocol)
  - In MESI protocol, transition from M to S requires flush to memory
  - Instead transition from M to O (O="owned, but not exclusive") and do not flush to memory
  - Other processors maintain shared line in S state, one processor maintains line in O state
  - Data in memory is stale, so cache with line in O state must service cache misses
  - Used in AMD Opteron

Implications of implementing coherence

- Each cache must listen for and react to all coherence traffic broadcast on interconnect

- Additional traffic on chip interconnect
  - Can be significant when scaling to higher core counts

- Most modern multi-core CPUs implement cache coherence

- To date, GPUs do not implement cache coherence
  - Thus far, overhead of coherence deemed not worth it for graphics and scientific computing applications (NVIDIA GPUs provide single shared L2 + atomic memory operations)

Implication of coherence implementation to software developer: artifactual communication

What is the potential performance problem with this code?

```
// allocate per-thread variable for local per-thread accumulation
int myCounter[NUM_THREADS];
```

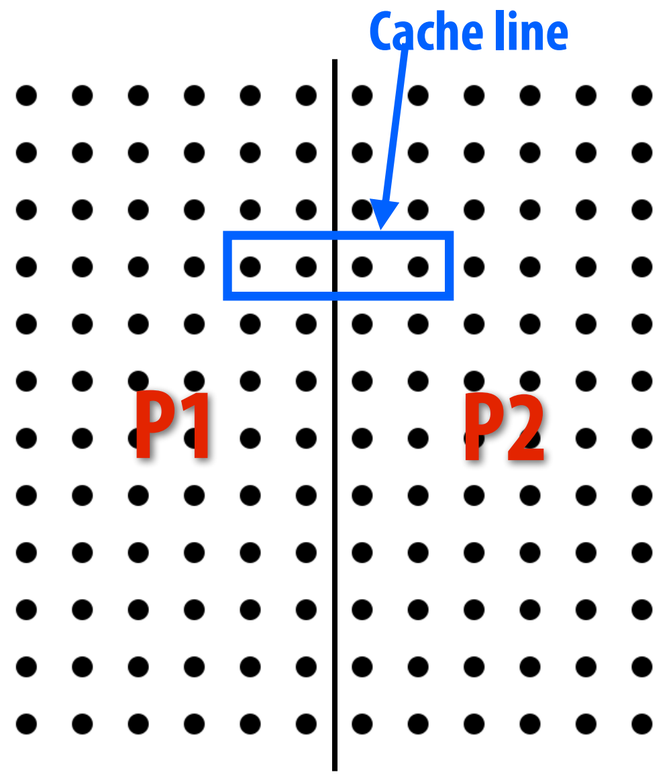
Better:

```
// allocate per thread variable for local accumulation
struct PerThreadState {
  int myCounter;
  char padding[CACHE_LINE_SIZE - sizeof(int)];
};
PerThreadState myCounter[NUM_THREADS];
```

False sharing

- Condition where two processors write to different addresses, but addresses map to the same cache line

- Cache line "ping-pongs" between caches of writing processors, generating significant amounts of communication due to the coherence protocol



- No inherent communication, this is entirely <u>artifactual communication</u>

- False sharing can be a factor in when programming for cache-coherent architectures

Summary

- The cache coherence problem exists because the abstraction of a single shared address space is not actually implemented by a single storage unit in a machine
  - Storage is distributed among main memory and local processor caches
  - Data is replicated in local caches for performance

- Main idea of snooping-based cache coherence: whenever a cache operation occurs that could affect coherence, the cache controller broadcasts a notification to all other cache controllers
  - Challenge for HW architects: minimizing overhead of coherence implementation
  - Challenge for SW developers: be wary of artifactual communication due to coherence protocol (e.g., false sharing)
